### ABSTRACT

This study proposed the creation of an algorithm for the elaboration of a midsole customized by functional parameters and generative systems, with production through digital manufacturing. The computational resources used are the Rhinoceros® program and the Grasshopper® extension. The primitives are given in a ".asc" format for the plantar pressure distribution test; the position of the insole sensors (.jpeg); 3D geometry of the midsole parameterized from the outline of a common insole. The developed algorithm operates by converting midsole geometry (brep) into point cloud complemented with a point cloud based on the position of the sensors and the remapped values of maximum pressure into integer numbers. Voronoi 3D component cell structure is generated by the overlapping point clouds. Based on the incorporation of an external algorithm, it was possible to obtain an open cell mesh structure. The digital manufacturing of the geometry was tested through three-dimensional printing similar to the Fused Deposition Modeling (FDM) process in rigid lactic acid (PLA) and flexible thermoplastic polyurethane (TPU). It was observed in the model printed on flexible material that the increase in the density of cells in the regions of greater pressure contributes to the increase in local stiffness, which may imply the individualization of the functional requirements of footwear. Nine customization possibilities are presented by changing three different variables, related to the density of points of the base geometry and the conversion of pressure values. The third variable was the thickness of the final structure as a function of the volume scale and faces of the three-dimensional cells generated by the 3D Voronoi. It is concluded that the import of real data from biomechanical testing for parametric modeling in Grasshopper® could contribute to the design of shoes individualized by the aesthetic and functional requirements of each consumer.

## Exploração do design de entressola por algoritmo baseado em dado biomecânico e Voronoi 3D para fabricação digital.

### RESUMO

Este estudo propôs a criação de um algoritmo para elaboração de uma entressola customizada por parâmetros funcionais e sistemas generativos, com produção através da fabricação digital. Os recursos computacionais utilizados são o programa Rhinoceros® e a extensão Grasshopper®. As primitivas são dados em formato ".asc" de ensaio de distribuição de pressão plantar, posição de sensores da palmilha (.jpeg) geometria 3D de entressola parametrizada a partir do contorno de uma palmilha comum. O algoritmo desenvolvido opera pela conversão de geometria de entressola (brep) em nuvem de pontos complementado com nuvem de pontos derivada da posição dos sensores e valores re-mapeados de pressão máxima. Pela sobreposição das nuvens de pontos é gerada estrutura celular do componente Voronoi 3D. Com base na incorporação de algoritmo externo foi possível obter uma estrutura de malha de células abertas. Foi testada a fabricação digital da geometria através da impressão tridimensional similar ao processo *Fused Deposition Modeling* (FDM) em poliácido láctico (PLA) rígido e poliuretano termoplástico (TPU) flexível. Foi observado no modelo impresso em material flexível que o aumento da densidade de células nas regiões de maior pressão contribui para o aumento rigidez local, podendo implicar na individualização dos requisitos funcionais do calçado. É apresentado nove possibilidades de customização pela alteração de três variáveis distintas, relativas à densidade de pontos da geometria base, e da conversão de valores de pressão; e espessura da estrutura final em função da escala de volume e faces das células tridimensionais geradas pelo voronoi 3D. Conclui-se que a importação de dados reais de ensaio biomecânico para modelagem paramétrica no Grasshopper® contribui para o projeto de calçados individualizado pelos requisitos estéticos e funcionais de cada consumidor.

## 1. INTRODUCTION

Vision prospects of the industry future path indicate to product customization by individual attributes, with economic feasibility achieve by efficient and modular manufacturing systems applied on demand (FETTKE et al., 2014). The advanced growing demand for custom products besides life-cycle market time reduction were resulting in complexity problems and opportunities for structural change of industrial sector (BRETTEL et al., 2014). An opportunity are smart products and machines, designs based in computational innovate technology applied to project development phases as analysis, simulation, optimization, manufacturing and remote control (VOLPATO, 2007; FETTKE et al., 2014). Volpato (2007), orients of product market success is correlated to clarify capacity in identification of user demand as equal to project good quality solutions for their needs.

The footwear industry has been changing by combine technologies of software or digital development and traditional manufacturing (RAFFAELI, GERMANI, 2011). Feijs et al. (2016), researched the technical feasibility to customize footwear sole, based in user collaboration, generative algorithms and digital manufacturing. Footwear brands as Adidas, New Balance and Under Armor (Figure 1) have been developing similar technologies to functional midsole design.

**Figure 1** Midsole designs oriented to digital manufacturing, created by Adidas (a), (2018); New Balance (b), (2016); and Under Armor (c), (2018).

The Adidas midsole (Figure 1a) was data-driven designed using biomechanical data from athletes and a process that possibility control almost 20.000 lattice structures as possible to optimize foot stability on running activity (ADIDAS, 2018). The New Balance midsole applied an open cellular multivariable size geometry focused in optimize flexibility, stiffness, weight and extend lifetime (NEW BALANCE, 2016). The Under Armor technology applied to midsole is composed by a dynamic lattice structure, designed to improve cushioning and user foot support (UNDER ARMOR, 2018).

In this horizon of technology applications, refer Feijs et al. (2016) article that 3D modeled a custom sole through generative algorithm to achieve conceptual geometry inspired on Voronoi diagram. In the article, the 3D model was submitted to digital manufacturing process by Fusion Deposition Modeling® (FDM) technology with flexible filament (FEIJS et al., 2016).

### 1.1 Plantar Pressure Data

Footwear consumers have been presenting feet healthy concerns, demand understood by specialists as crossing biomechanics and aesthetic parameters (SANTOS; ÁVILA, 2007). Footwear sole as fundamental component of shoes has propose to protect the feet by absorbing ground forces generated by the impact on ground in run or walk movement (PALHANO, 2013). Footwear biomechanics studies target the correlation between reduce plantar pressure distribution peaks as relevant improve to prevent disease, when provided correct support to feet anatomy (CHEUNG; ZHANG, 2006). The evaluation of plantar pressure distribution depends of footwear

usability, low pressure values are positive to impact force dissipation and contribute to cushioning and support, however, high pressure values are positive when related to feeling and performance attributes in running or trail events (IBTEC, 2018).

According of CHATZISTERGOS et al. (2017) analysis, reduce plantar pressure by material selection are in general guided by material stiffness, although this method is strongly influenced by magnitude of the applied forces. The applied forces maximum values are obtained in biomechanics analysis are divided in two main peaks, the first is measured in the first half time and indicates the maximum vertical force of ground reaction; the second peak measured in the second half of time of contact are result of muscular activity generated to lift the feet (PALHANO, 2013 apud NIGG & HERZOG, 2007). The data generated in biomechanics analysis of feet plantar pressure are provided by sensor insoles, the values are correlated to each sensor position and collected at specify time frequency (CEZAR et al., 2003). CEZAR et al. (2003), indicates that custom insoles could be applied to maintain an homogenic pressure distribution, as way to reduce feet stress derivate by magnitude values higher than 2800 g/cm<sup>2</sup>.

### 1.2 Generative Systems

In recent years, project innovative methods are feasible by development of new tools and computational technologies. Technology is disrupting new paths toward to multiple shape generation in product design (AGKATHIDIS, 2016). The generative system is part of techniques collection, in the path were searches to explore and resolve problems of the initial or final ideation process, oriented to manipulate algorithms as mean to produce unique shapes (MARTINO, 2015).

The product or output of a generative system are not constrained by a singular tool application (FISCHER; HERR, 2001). The output of generative process converges a collection of parameters, basically correlated each other by predetermined conditional rules (MARTINO; CELANI, 2014). The processing transformation are feasible by implementing parametric tools, as examples the Rhinoceros® software and Grasshopper® plug-in. Complementing collection of digital tools of both software, is possible to generate a high degree complexity of surfaces or shapes. The topological complexity is variable by mutation of the initial collection of geometry described as primitives, an example, point and curves objects (FLORIO, 2011).

### 1.3 Digital Manufacturing

Our society is living the vanguard of the 4th industry revolution, the rapid prototyping defined the application of new technologies to make feasible to manufacture complex geometries, further, recent advances in 3D printing are contributing to achieving near on-demand production level as rapid manufacturing applications (VOLPATO, 2007; HUANG et al., 2015). The digital manufacturing process is classified by raw material initiate stage as liquid, solid and powder, as well the nomenclature synonyms are additive manufacturing (AM), additive processes, layer manufacturing and freeform fabrication (VOLPATO, 2007; HUANG et al., 2015).

Additive manufacturing processes include stereolithography (SLA), selective laser sintering (SLS), fused deposition modeling (FDM), and others (HUANG et al., 2015). As previous footwear midsoles technology examples in Figure 1, Adidas 4D was manufactured by Carbon CLIP™ technology of Digital Light System, as liquid resin-based technology (CARBON, 2020); New Balance and Under Armor were manufactured by SLS process, based in thermoplastic elastomer powder (NEW BALANCE, UNDER ARMOR). As solid based technology FDM applied by Feijs et al (2016), the geometry is created layer by

layer of fusion and deposition of thermoplastic filament (VOLPATO, 2007).

This process requires support structure to manufacture void geometries, the structure should have mechanical properties to support the principal element, as weak to be removed by hand tools or dissolution by immersion (VOLPATO, 2007). Advantages of AM process area feasibility to produce on-demand for customization, heterogeneous composition, and complex structures design, decreasing of material waste production, and mechanical properties performance as 85% to achieved by injection molding technology (VOLPATO, 2007; HUANG et al., 2015).

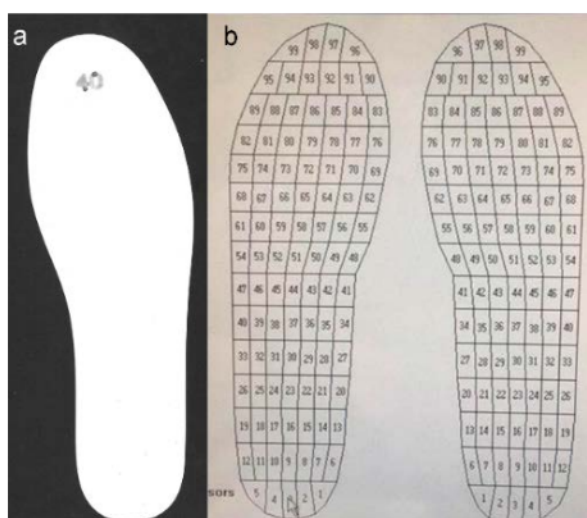

In this article, the research objective was improving Feijs et al. (2016) concept through the development of a new generative algorithm to 3D modeling a data-driven custom midsole, inspired in Voronoi diagram and manufacturing by a digital process similar to FDM<sup>®</sup>. The opportunity to combine feet plantar pressure data and the generative system would contribute to individualize performance attributes in custom midsoles designs.

## 2. MATERIALS AND METHODS

The algorithm design was performed in Rhinoceros<sup>®</sup> software and Grasshopper<sup>®</sup> plug-in tools. In the develop process was necessary insert an external pre-existent algorithm "voronoi test.gh" created by Michael Pryor, the file was freely downloaded from Grasshopper online forum (GRASSHOPPER3D, 2012).

### 2.1 Primitives

The start step to algorithm design is to define primitives, as references that are imported to Grasshopper<sup>®</sup> visual programming environment. To create the midsole was defined as primitives a generic insole edge curve, was drawn a contour based on referenced image (Figure 2a) of a digitalized an 40 French scale or 9 in US scale, insole sample extracted directly by the shoe last manufacturer.

**Figure 2** Digitalized insole contour (a) and sensor referenced position per insole (b).

The second primitive was raw data (.asc) from biomechanics analysis of plantar pressure distribution (Baropodometry) with pressure values (KPa) as function of frequency rate (0.2 seconds). At end, the third primitive is an image (.jpeg) of the referenced position of 99 pressure sensors (Figure 2b) per insole.

### 2.2 3D Printer

To materialize the output midsole geometry from the generative process, was performed two phase of Fused Deposition Modeling techniques. At first was made reduce scale model in Polylactic Acid (PLA) filament, 1.75 mm diameter, in 3DCloner<sup>®</sup> DH equipment and print area of 320 x 200 mm, disponible at workshop of the Architectural Faculty (UFRGS). The second phase was contract third party print services by PrintUp 3D company, when a real scale model was printed by FDM process in white-translucent TPU filament, 90 Shore A hardness. In Zortrax<sup>®</sup> Equipment.

## 3. RESULTS AND DISCUSSION

The presentation of result is segmented in two phases, first the algorithm development and second the materialization process. The algorithm development is subdivided in plantar pressure data import to grasshopper environment, parametrization of the insole sensors position, generic midsole geometry, primitive's conversion to point cloud, 3D cellular geometry based in Voronoi 3D component and refine lattice 3D mesh. The materialization process was performed inhouse first, in PLA and second in TPU by a commercial partner.

### 3.1 The Contour Primitive

To define the midsole top view curve contour (Figure 3) was imported a generic jpeg image with the background bitmap Rhinoceros<sup>®</sup> tool in the top viewport and drawn on the image, by interpolate curve the desired contour. In Grasshopper<sup>®</sup> environment creates a primitive curve component referenced on that curve

### 3.2 Import Biomechanics Data

The challenge was import result data of biomechanics analysis to Grasshopper<sup>®</sup> (Figure 3) environment. The Readfile component was capable to read the available .asc file, defined as input the directory and name file (C:\), the component extracts data per line in a list indexes and characters, it could visualize by panel as output. Based in the list, is apply split list component as "10" index to separate the label chart names (A output) and the raw data of each insole sensor (B output). In raw data the to extract sensor data per index, was broke the lists structure by split text component as "" input. In the resultant lists, the null or empty lines was removed by cull pattern component, as pattern input was obtained by compare the list to a number superior of the data in the list, as example was applied "400", by the inequality output is extract the true/false list that defines the cull pattern. The result lists is split on "98" index to separate the left (A output) and right (B output) foot data, resulting in 251 lists with 99 indexes.

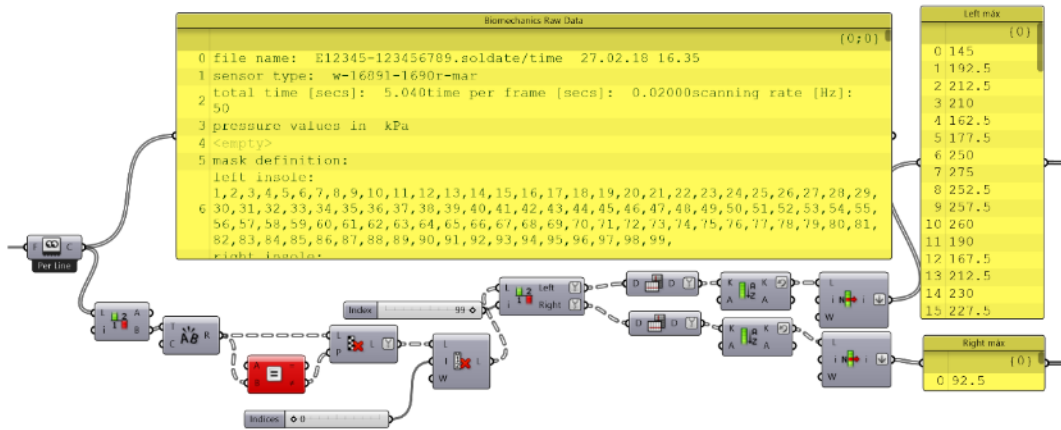

Figure 3 Pressure data read file per line and components steps isolate as flatten list, the maximum values per sensor.

Finally, to extract the maximum value per sensor is applied the sort list component to reorganize the values in crescent order, as sort list “K” output is inverted for through list item component with index equals to “0” the output of list item is the high pressure value collected (data) per each sensor (index).

**3.3 Insole sensor parametrize**

The maximum pressure values isolated in previous steps, are organized in a specific order and location based in original sensor insole equipment, originally applied to collect the biomechanics data. To match the order and location of each index of the lists with correspond insole sensor, the sensor grid is drawn based an image reference (Figure 2b).

The procedure (Figure 4) was extract three (lateral, front and back) edges lines from the bounding box of the primitive

curve; divide the curves line-type in 15, 8 and 10 points, respectively. Next was removed the first and last point of the lateral point list by Cull Index tool (index 0 and 15), as well was selected the front point list by panel with index (5, 6, 7) and back point list by panel with index (3, 4, 5, 6). Based in the length of back bounding box edge defines the length of a group of lines obtained by Line SDL tool, as culled lateral list the start points, X direction. To split the new line list is reversed for re-orientation and applied Curve Line (CLX) intersection tool between group lines and primitive curve, the resulting intersection points list are in 28 branches with 2 items each. To define lines inside primitive curve regions, the list is split to isolate the in A and B output inserted in A and B inputs of Line (Ln) tool.

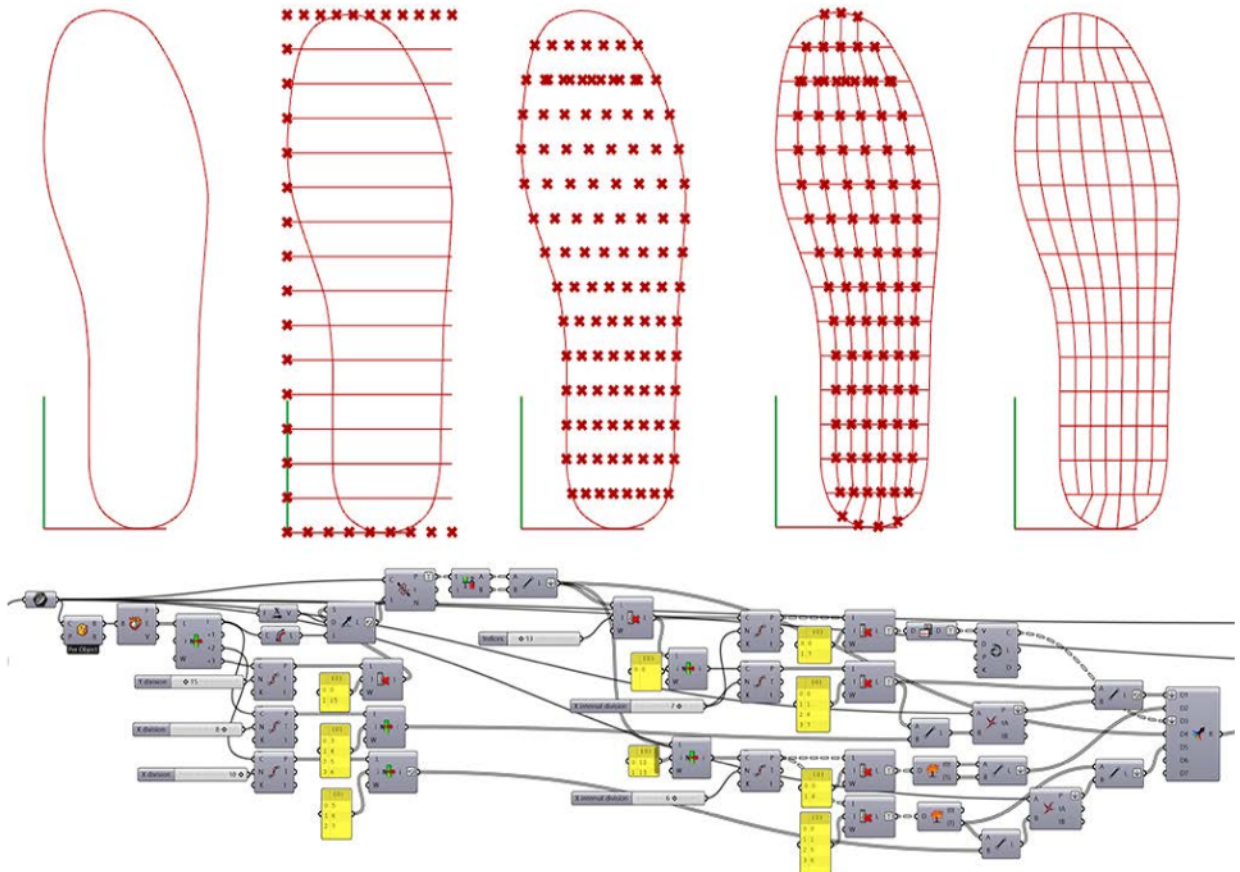

Figure 4 Visual preview and algorithm sequence to parametrize the location of the sensors in enumerate position similar to Figure 2b primitive.

Based in the flatten of the group of lines transversal to primitive curve orientation, was performed three actions. First, cull the last list index (13) and divide by 7 points the branched 13 lines, was removed the first and last points by index (0, 7) and inverted of transversal to longitudinal distribution with Filp Matrix tool (6 branches with 13 points), and finally by Interpolate Curve (IntCrv) defining 6 longitudinal curves. To create the front longitudinal lines, the two last index curves of the transversal list is listed and divided by 6. The two transversal curves of front are listed by index (12 and 13) and divided in 6 points list; points are removed in two ways by the cull index (0, 6) and (0, 1, 5, 6), branches are exploded with Explode Three component. In one way the points in both lines are connected creating 5 longitudinal lines, in the second way the most front points are connected with the previous list of three point extracted of the bounding box front edge, it was reverted lists to align, resulted in three lines. Simpler, the back longitudinal lines result of division of the first line (transversal) listed by index (0) in a list with 7 points, are culled the point index (0, 1, 6, 7) to isolate intermediary points that are connected with listed output points of back bounding box edge, inverted to aligned, the four new lines are crossed by Curve Curve (CCX) tool with the primitive curve, finally the resulting points are connect with the intermediary points to define the last grid lines. From last steps are defined 4 lists longitudinal lines, all was flattened and merge with the transversal lines to define a grid capable to reproduce de sensor position (Figure 2b).

Figure 5 Algorithm sequence to split the insole boundaries surface into 99 trimmed surfaces, index items adjust to correct order and finally mirror operation.

The grid of merged lines is input to Surface Split (SrfSplit) component, as well a boundary surface based in primitive curve (Figure 5). After split are obtained 99 trimmed surfaces, the centroid location is extracted by area component, it was necessary to organize the first and last position by cull, list and insert items components. To finalize the sensor parametrization is merge in three branch lists the 99 trimmed surfaces, 99 centroid points and the original primitive curve. As example to show the high-pressure values obtained, based in CEZAR et al. (2003) indication of acceptable values under 2800 g/cm<sup>3</sup> or approximately 274 KPa (MATH.TOOLS, 2019), it was defined a gradient preview for each feet result, the results

(Figure 6) clarify in pure red the sensors that reach values above 274 KPa, the limit value referenced.

Figure 6 Gradient color preview of the maximum value for each sensor.

### 3.4 Midsole Brep

To create the cloud point that could be combined with the cloud originated by the pressure values and together define an input for Voronoi 3D component, it was parametrize a generic midsole brep. Are not focus made and detailed model, so the process was basic to define a bottom and top view countour by dividing the lateral bounding box edge in 5 points, moving by arbitrary values in Z direction and defining the bottom curve by Interpolate (IntCrv) and top curve from Nurbs Curve (Nurbs). For better grip with the table in 3D print, it was defined a planar bottom, the top contour is referenced in the higher heel to absorb energy and low front to be responsive.

To extrude the contours, it was moved 10 points in negative X direction, and as extrude factor use X direction and the length is based in bottom bounding box edge of primitive curve plus 40 points by slider component. The primitive curve is project on both surfaces and used as trim parameter in Surface Split (SrfSplit) to defines the top and bottom surfaces. To end this procedure, it was made a loft surface by bottom and top projected curves, was applied custom options to make a uniform surface. The three resulting surfaces are merged and combined by Brep Join (Join) component to define the midsole brep (Figure 7).

Figure 7 Algorithm to obtain the midsole closed brep based in insole primitive curve and the extrusion of parametrized side view curves.

### 3.5 Cloud Points Based in Pressure Values

The primitive curve, 99 grid surfaces, 99 centroid points, the midsole brep and its top surface are organized in primitive components for next steps, all elements are made one time in algorithm running and mirror to define the opposite feet primitives.

For this article we aimed to present the feasibility to transform pressure data in point quantity to define a cloud point, we define a proportional density of points as function of high-pressure values. However as referenced by Palhano (2013), in the step movement are two main peaks of force, first in back region associate to impact energy dissipation (cushiness) and second peak on front relative to muscular energy transmission. Duo the research intention in explore and validate the whole process of modeling a midsole geometry by a data driven algorithm to result in digital manufacturing, it was simplified by applied proportional point density in back and front peaks regions. The applied logics it was a remap pressure values with Remap Numbers component with input value as

max pressure list, source as respectively bounds (domain) and target as constructed domain between 0 to 10.

Cloud points are defined by Populate Geometry (PopGeo) component in two steps, first as geometry input is the 99 trimmed surfaces and count input as remap number pressure result converted only in integer values by integer component, to define 99 listed clouds. Second, as input the midsole brep and as quantity a slider, it was defined 100 to balance between a low and higher structure complexity that will be impact in time processing to generate the Voronoi cells and mesh lattice. The populate clouds of the first step created in XY plane is projected to midsole top surface by Project Point (Project) component in Z direction. It is relevant to highlight the primitive curve are applies as guide to sensor parametrization as well the midsole top surface design, allowing to project the cloud point as correct location in the 3D top surface. The 99 clouds output are flattened and merged with the midsole-based cloud in one list (Figure 8), this phase is running separate for each foot, to match with each feet pressure data. .

**Figure 8** Above visual preview, below algorithm sequence to define the biomechanics based cloud point (selected) plus cloud point from midsole closed brep; voronoi cells after solid intersection; open cell brep structure and baked Weavebird's Loop Subdivision mesh.

### 3.6 Voronoi 3D and Mesh Lattice

The Voronoi 3D (Voronoi<sup>3</sup>) component demands as inputs a point list that will determine the cell quantity, as points defines the centers of each 3D cell and its distribution pattern the cell size and boundaries. As point input it was connected to the cloud points merged previous steps.

The voronoi 3D runs creating a 3D box with the respective quantity and distribution of cells based in the point list coordinates. Split in the midsole shape is performed by Solid Intersection (SInt) component as input A the Voronoi output and input B the midsole brep, this order is important to extract the aimed result. It was faced output difficulties of open Voronoi cells when the Voronoi box are some of the bounding box volume of midsole brep, to avoid it was extracted the midsole brep bounding box and re-scaled to bigger size by a factor equals to "1.1". Is possible to observe in Figure 8

components, the Voronoi original box, re-scaled larger than midsole brep and final solid intersection result (Figure 8).

Initially it was focused in produce some lattice structure inspired by New Balance midsole example referenced at introduction of this article, it was attempted to apply the Pipe and Pipe Variable (VPipe) Grasshopper® native components to add thickness to the edge lines of the Voronoi cells. The attempt faced difficulties as the duplicate curve edges by overlapped faces between the cells as result of deconstruct brep of Voronoi 3D output, this quest was overcome by download of Remove Curve Duplicates component found in Grasshopper online forum and download from MilkBox group. Although achieve success to simplify the edge list count, the pipes are creating as independent tubes geometry and not as network structure resulting in lack of surface continuity. This problem resulted in rhinoceros model file size larger than 100

Mb depending of quantity of cells, higher density comes close to 500 and 800 Mb files. The large file size failed to export in STL format and to be interpreted by 3D print CAM software.

After the related experience, it was found an algorithm designed by Michael Pryor and free download available that was successful applied to resolve the meshing and exporting process. Next, a brief explanation of this algorithm components and running that made possible to connect re-scaled curves extracted from edge and face cell elements. There necessary defines three inputs to run this step, one or more closed polysurfaces, a control thickness factor (slider) with bounds between 0 and 1 with four digits rounding ("0.6000") for the scale faces and other similar control thickness factor for scale volumes. As closed polysurface are input the Voronoi cells as single flatten list, and scale factors equals to "0.6000".

The algorithm works transforming the geometry based in the extract edges of cell scaled faces and volume, join coincident curves, and creating loft surfaces between rescaled face edges with the original cell edges and the rescaled volume edge. The two loft surface outputs are joined by Brep Join (Join) component in open surfaces. The next algorithm segment works to resolve the same problem explained above about overcome cell faces that duplicate the total data. Finally, all brep surfaces are joined in one single closed brep, to export as STL file it was transformed in a mesh geometry by Mesh Brep (Mesh) component and round the edges by Weaverbird Loop Subdivision (wbLoop) with 1 as level input (Figure 8). Finally, each foot correspondent mesh is baked as ID geometry in Rhinoceros environment. Figure 9 reveal the superior individualized profile results for each foot as based in biomechanics data primitive, and Figure 10 the bottom profile standard for both midsoles.

Figure 9 Top profile of baked meshes, independent cell pattern for left and right midsoles.

Figure 10 Standard cell pattern in bottom profile.

### 3.7 Digital Manufacturing

The digital manufacturing by FDM technique was performed first at workshop facilities of the Architecture Faculty (UFRGS), and secondly by third partner startup company named Printup3D. To CAM process, the file size was reduced by reducing the mesh face count with Rhinoceros Reduce Mesh tool in 90% less faces than the original count. In this process it was realized the presence of naked edges and manifold edges, it was identified by Rhinoceros Mesh repair wizard and manually removed these elements by the tool resources.

To optimize filament, use and produce time, was defined a nonsupport material structure, that represents no problem at end. Was prototype two models in PLA, first with base support and second with front elevation. Both geometries were successful printed in approximately 8 and 11 hours (Figure 11).

Figure 11 Pictures of 3D printing samples in blue PLA filament, and final geometries.

Next it tried to print in TPU at Architecture facility, but it was found problems in the feed filament mechanics, as the filament round by the traction wheel. To resolve was determined to use external expertise by the PrintUp3D Startup, they successfully printed in white TPU filament, 90 Shore A hardness, as can be observed at Figure 12. Due open cell structure and absence of support material it is notice some filament trays resulting in medium finish quality.

Figure 12 Pictures of 3D printing final geometry in white-translucid and flexible TPU.

### 3.8 Custom midsole designs

Achieve successful digital manufacturing was set as a goal to validate the parametric model algorithm. Based on the described primitives and input variables presented at this point, this section will be discussed the range of options to customize

the geometry. Firstly, to customize the density and size of Voronoi 3D cells, was modify variables as populate geometry count input, for midsole brep and biomechanics data conversion. Secondly to define the lattice brep thickness is modify together and separately the scale face and volume factors of Michael Pryor algorithm. At this point is interesting to detail the run time of the algorithm sequences, because in development it was observed that increasing cloud point sizes directly affects the complexity and processing time of Voronoi structure and lattice brep creation, at a certain level to crash the Rhinoceros active document. In the example geometry defined in previous figures, it was determinate 100 points count to midsole popGeo; popGeo cloud point count of biomechanics data conversion in 0 to 5 bounds domain for each

sensor; scale face and volume factor sliders equals to 0.6000. For these parameters, the run time of preview off components takes 21,5 seconds for reading biomechanics data file and isolate maximum values; less than 1 second to align primitive curve, parametrize sensor position and create midsole brep; 18,8 seconds to define cloud points to Voronoi solid intersection of both midsoles; 151,9 seconds to run Michael Pryor's algorithm for both feet; 225,4 seconds to convert each brep to a mesh and 6 seconds for final WbLoop mesh.

The customized midsole designs are compiled in Figure 13, In three-row (variables) and four columns (values) structure of resulted baked meshes on render preview. Are choose arbitrary values to illustrate nine customizable alternatives.

**Figure 13** Custom designs modification by input variables as (a) midsole brep populate geometry points count; (b) biomechanics based cloud point size; (c) lattice thickness by scale faces and volume factors.

#### 4. CONCLUSIONS

The article was conducted as an experimental approach, it was accomplished the objective to design a Grasshopper® algorithm to model a custom midsole driven by biomechanics data primitives.

The success to import plantar pressure data and parametrize of sensor insole position accomplished with Grasshopper® native components. This procedure is the main contribution of the article, as the possibility to design geometry based on real biomechanics analysis results. The use of such data and sensor location could be contributed to apply Finite-Element Analysis (FEA) and topology optimization by Millipede Plugin resources as a complement to Grasshopper® component portfolio. The strategy to transform max pressure values in integer numbers as quantity input to cloud populate had an experimental objective to reveal the pressure distribution. The authors intended to correlate the local geometry density (cells) as a cause to increase local stiffness, the result that was observed in TPU printed geometry.

The Voronoi 3D component can generate an individualize aesthetic, however, it increases the final geometry complexity and processing time. It was necessary to import a preexistent algorithm to resolve the complexity in on single closed mesh. The main variables of the algorithm are pressure plantar data; insole contour curve, cloud point sizes, and distribution rescale cell volume and face factors. The generative algorithms are a standard reality nowadays with potential do provide feasibility to footwear components customization by functional primitives. The developed algorithm presented in this article is a contribution as an application in midsole design that could improve the general consumer's health.

#### 5. ACKNOWLEDGMENT

This study was financed in part by Coordenação de Aperfeiçoamento de Pessoal de Nível Superior - Brasil (CAPES), Finance code 001. The algorithm development was conducted on Design and Material Selection Laboratory (LdSM) and Engineering School Innovation and Digital Manufacturing Laboratory (LIFELAB), both in UFRGS. The data file of plantar pressure (.asc) and sensor position image (.jpeg) are a contribution of Ph.D. Rudnei Palhano from Biomechanics Laboratory of the Brazilian Technology Institute of Leather, Footwear and Artifacts (IBTeC).
